ABSTRACT

We discuss a new type of dust acceleration mechanism that acts in a turbulent magnetized medium. The magnetohydrodynamic (MHD) turbulence can accelerate grains through resonant as well as nonresonant interactions. We show that the magnetic compression provides higher velocities for super-Alfvénic turbulence and can accelerate an extended range of grains in warm media compared to gyroresonance. While fast modes dominate the acceleration for the large grains, slow modes can be important for sub-micron grains. We provide comprehensive discussion of all the possible grain acceleration mechanisms in interstellar medium. We show that supersonic velocities are attainable for Galactic dust grains. We discuss the consequence of the acceleration. The implications for extinction curve, grain alignment, chemical abundance, etc, are provided.

Key words: dust, extinction–ISM: particle acceleration–kinematics and dynamics–magnetic fields.

1 INTRODUCTION

Dust is an important constituent that is essential for heating and cooling of the interstellar medium (ISM). It interferes with observations in the optical range, but provides an insight to star-formation activity through far-infrared radiation. It also enables molecular hydrogen formation and traces the magnetic field via emission and extinction polarimetry (see Hildebrand et al. 2000; Lazarian 2007). The basic properties of dust (optical, alignment etc.) strongly depend on its size distribution. The latter evolves as the result of grain collisions, whose frequency and consequences (coagulation, cratering, shattering, and vaporization) depend on grain relative velocities (see discussions in Draine 1985; Yan, Lazarian, & Draine 2004, hereafter YLD04; Hirashita & Yan 2009).

All these problems require our understanding of grain motions in the interstellar medium. The interstellar medium is magnetized and turbulent (see Arons & Max 1975). Although turbulence has been invoked by a number of authors (see Kusaka et al. 1970; Voelk et al. 1980; Draine 1985; Ossenkopf 1993; Weidenschilling & Ruzmaikina 1994) to provide substantial grain relative motions, the turbulence they discussed was not magnetized. Dust grains are charged, and their interactions with MHD turbulence is different from the hydrodynamic case.

In Lazarian & Yan (2002) and Yan & Lazarian (2003, henceforth YL03), we considered acceleration of charged dust by the MHD turbulence. In particular, Lazarian & Yan (2002) applied the theory of Alfvénic turbulence (Goldreich & Sridhar 1995, henceforth GS95, see Cho, Lazarian, & Vishniac 2003, for a review) to grain acceleration through gaseous drag; YL03 identified a new mechanism for grain acceleration through gyroresonance. In

YLD04, we showed that the acceleration by turbulence dominates over other processes and can provide supersonic speed to the grains. On the other hand, it is known (Spitzer 1976; Shull 1978; McKee et al. 1987; Ellison, Drury, & Meyer 1997) that grains can also be efficiently accelerated through betatron process by the compressions at shocks. In this paper, we shall consider the betatron acceleration of dust by both incompressible and compressible turbulence. The intent is to provide a comprehensive view of current understanding of grain dynamics in MHD turbulence.

To describe the turbulence statistics we use the analytical fits to the statistics of Alfvénic modes obtained in Cho, Lazarian, & Vishniac (2002) and compressible modes obtained in Cho & Lazarian (2002, hereafter CL02), which is consistent with the spectra of turbulence velocity from observations (Lazarian 2008). In §2, we provide a brief description of the relevant properties of MHD turbulence. In §3, we study acceleration by large scale turbulence, where acceleration in both collisionless and collisional regimes are discussed. In §4, a review of alternative acceleration mechanisms is presented. In §5, we apply the results to interstellar grains and give a comparison of different mechanisms. Implications of our results are included in the discussion of in §6, while the summary is provided in §7.

2 MHD TURBULENCE AND ITS STATISTICAL PROPERTIES

Turbulent acceleration may be viewed as the acceleration by a spectrum of MHD waves that can be decomposed into incompressible Alfvénic, and compressible fast and slow modes (see CL02). Separation of MHD perturbations in compressible media into fast, slow and Alfvén modes is discussed in GS95, Lithwick & Goldreich (2001), and CL02. The actual decomposition of MHD turbulence

^{*} E-mail: yan@lpl.arizona.edu

into Alfvén, slow and fast modes was performed in CL02, who also quantified the intensity of the interaction between different modes (see below). Unlike hydrodynamic turbulence, Alfvénic turbulence is anisotropic, with eddies elongated along the magnetic field. This happens because it is easier to mix the magnetic field lines perpendicular to the direction of the magnetic field rather than to bend them. As eddies mix the magnetic field lines at the rate $k_{\perp} v_k$, where $k_{\perp}$ is the perpendicular component of wavenumber k , v_k is the mixing velocity at this scale, the magnetic perturbations (waves) propagate along the magnetic field lines at the rate $k_{\parallel} v_A$, where $k_{\parallel}$ is the parallel component of the wave number k , v_A is the Alfvén speed. The Alfvénic turbulence is described by GS95 model. The corner stone of the GS95 model is a critical balance between these rates, i.e., $k_{\perp} v_k \sim k_{\parallel} v_A$, which may be also viewed as coupling of eddies perpendicular to the magnetic field and wave-like motions parallel to the magnetic field. From these arguments, the scale dependent anisotropy $k_{\parallel} \propto k_{\perp}^{2/3}$ and a Kolmogorov-like spectrum for the perpendicular motions $v_k \propto k^{-1/3}$ can be obtained. It was conjectured in Lithwick & Goldreich (2001) that the GS95 scaling should be approximately true for Alfvén and slow modes in moderately compressible plasma. For magnetically dominated, the so-called low β plasma, CL02 showed that the coupling of Alfvén and compressible modes is weak and that the Alfvén and slow modes follow the GS95 spectrum. This is consistent with the analysis of observational data (Lazarian 2008) as well as with the electron density statistics (see Armstrong, Rickett, & Spangler 1995). According to CL02, fast modes evolves separately and are isotropic.

Depending on whether the turbulence velocity on the energy injection scale L_{inj} , δV is larger or smaller than the Alfvén speed, turbulence can be either super-Alfvénic ($M_A \equiv (\delta V/v_A) > 1$) or sub-Alfvénic ($M_A < 1$). Turbulence is considered super-Alfvénic in intracluster medium. Although less certain, the interstellar turbulence may also be in this regime (Beck 2001; Padoan et al. 2004). Super-Alfvénic turbulence evolves with hydrodynamic Kolmogorov cascade till the scale $L = L_{inj}(\delta V/v_A)^3 \equiv L_{inj}M_A^3$, where the turbulence velocity becomes equal to the Alfvén speed v_A^1 . Below this scale, magnetic field becomes dynamically important and the MHD cascade described above sets in.

We do not deal with the imbalanced turbulence (see Lithwick et al. 2007; Beresnyak & Lazarian 2008; Chandran 2008) in this paper, as the degree of imbalance in compressible interstellar is unclear. We consider all the turbulent energy is injected from large scales and do not include additional energy injection on small scales arising from compressions of cosmic rays (Lazarian & Beresnyak 2006). Note that the Alfvénic turbulence and slow modes are different from waves as they are short lived, only fast modes may resemble wave turbulence.

3 ACCELERATION OF GRAINS BY LARGE SCALE TURBULENCE

There exists an important analog between dynamics of charged grains and dynamics of cosmic rays (CRs) and we shall modify

the existing machinery used for cosmic rays to describe charged grain dynamics².

The energy exchange between the particles and the waves involves both resonant and nonresonant interactions. Resonant interaction was considered in YL03 and YLD04. Here we shall be investigating the role of nonresonant interactions on grain dynamics. The role of the non-resonant acceleration of CR by large scale compressions were discussed earlier (Berger et al. 1958; Kulsrud & Ferrari 1971; Ptuskin 1988), and further clarified for MHD turbulence in Cho & Lazarian (2006), but there are substantial differences between cosmic rays and grains. In particular, the gyroradii of grain are much larger and can get comparable to the correlation length of turbulence. Moreover, grains are moving much more slowly than the CRs and therefore scattering is not important. Mean free path l_{mfp} of grains are thus much longer and there exists a more important collisionless interaction regime with $l < l_{mfp}$, which we shall demonstrate is the dominant nonresonant interaction in the paper.

Apart from acceleration, a grain is subjected to gaseous friction. For the sake of simplicity we assume here that grains are moving in respect to stationary gas and turbulence provides nothing but the electromagnetic fluctuations. The acceleration of grains arising from the gas motion is considered separately (see LY02). We describe the stochastic acceleration of dust by the Brownian motion equation (see Kalmykov, Coffey, & Waldron 1996): $mdu/dt = -u/S + Y$, where m is the grain mass, u is the grain speed, Y is the stochastic acceleration force, $S = t_{drag}/m$ is the mobility coefficient (Draine 1985; Lazarian & Yan 2002). The drag time due to collisions with atoms is essentially the time for collisions with the amount of gas with the mass equal to that of the grain, $t_{drag}^0 = (a\rho_{gr}/n_n)\sqrt{\pi/(8m_nk_BT)}$, where a is the grain size, T is the temperature, n_n is the neutral density, ρ_{gr} is the mass density of grain. We adopt $\rho_{gr} = 3.8\text{gcm}^{-3}$ for silicate grains. The ion-grain cross-section due to long-range Coulomb force is larger than the atom-grain cross-section. Therefore, in the presence of collisions with ions, the effective drag time decreases by the factor (Draine & Salpeter 1979),

$$\alpha = 1 + \frac{n_H}{2n_n} \sum_i x_i \left(\frac{m_i}{m_n} \right)^{1/2} \sum_Z f_Z \left(\frac{Ze^2}{ak_BT} \right)^2 \ln \left[\frac{3(k_BT)^{3/2}}{2e^3|Z|(\pi x n_H)^{1/2}} \right]. \quad (1)$$

where n_H is the hydrogen density, x_i is the abundance, relative to hydrogen, of ion i with mass m_i , $x = \sum_i x_i$, and f_Z is the probability of the grain being in charge state Z . When the grain velocity gets supersonic (Purcell 1969), the gaseous drag time is given by $t_{drag}^s = t_{drag}/(0.75u/c_s + 0.75c_s/u - c_s^2/2u^2 + c_s^3/5u^3)$, where c_s is the sound speed.

Multiply the above Brownian equation above by u and take the ensemble average, we obtain

$$m \frac{d \langle u^2 \rangle}{dt} = - \frac{\langle u^2 \rangle}{S} + \langle \dot{\epsilon} \rangle, \quad (2)$$

Following the approach similar to that in Melrose (1980), we can get from Eq.(7) the energy gain rate $\langle \dot{\epsilon} \rangle$ for the grain

¹ Although in general turbulent generation of magnetic field which will bring kinetic and magnetic energy to equipartition, the dynamo process takes time and super-Alfvénic turbulence can appear as a transient phenomenon.

² In what follows we assume that the time scale for grain charging is much shorter than the grain Larmor period.

$$\langle \dot{\epsilon} \rangle = \frac{1}{4p^2} \frac{\partial}{\partial p} (up^2 D_p) \sim \frac{D_p}{m}, \quad (3)$$

where D_p is the momentum diffusion coefficient, and shall be derived below for different circumstances.

3.1 Acceleration in incompressible turbulence

One important nonresonant process is betatron acceleration. It arises from the compression of the magnetized fluid, which induces nonzero curl of electric field $\nabla \times \mathbf{E}$ in the plane perpendicular to the local magnetic field. The same betatron process was studied earlier in the context of shock acceleration, where grains are accelerated at postshock due to the compression. Here we shall investigate the betatron acceleration in turbulence. We stress that the betatron process operates even in incompressible turbulence, where magnetic field can be compressed by pseudo-Alfvén modes, which are the incompressible limit of slow modes.

Let us start with incompressible turbulence. The average electric field during one gyro-orbit can be estimated as (Cho & Lazarian 2006),

$$\begin{aligned} \bar{E} &= \frac{1}{2\pi r_g} \int (\nabla \times \mathbf{E}) \cdot d\mathbf{s}, \\ &= \frac{1}{2\pi r_g c} \int [\nabla \times (\mathbf{v} \times \mathbf{B})] \cdot d\mathbf{s}, \\ &\approx \frac{1}{2\pi r_g c} \int (\mathbf{B} \nabla \cdot \mathbf{v} - \mathbf{B}_0 \cdot \nabla \mathbf{v}) \cdot d\mathbf{s}, \end{aligned} \quad (4)$$

where r_g is the Larmor radius of grain, c is the light speed. The first term arises from the compression of the fluid, which is equal to zero in incompressible fluid. We approximate the total magnetic field $\mathbf{B}$ by the mean field $\mathbf{B}_0$ in the second term. We also used the fact that the MHD wave in incompressible medium is transverse, i.e., $\mathbf{v} \perp \mathbf{k}$. Therefore we focus here on the second term. In this case,

$$\bar{E} \approx -B_0 k_{\parallel} v_{k,\parallel} r_g / 2c. \quad (5)$$

, where $v_{k,\parallel}$ is the fluid velocity parallel to the magnetic field. The rate of momentum change is then

$$\frac{dp_{\perp}}{dt} = q\bar{E} \sim qB_0 k_{\parallel} v_{k,\parallel} r_g / 2c = p_{\perp} k_{\parallel} v_{k,\parallel} / 2. \quad (6)$$

where $q = Ze$ is the charge of grain and $p_{\perp}$ is the component of grain momentum perpendicular to the magnetic field. The acceleration is canceled out by the adiabatic loss in the parallel direction if the particle velocities are isotropic. Thus it only operates on the scale less than the mean free path l_{mfp} (Cho & Lazarian 2006), from which we get

$$D_p \sim \left(\frac{dp_{\perp}}{dt} \right)^2 \Delta t \sim p_{\perp}^2 (k_{\parallel} v_{k,\parallel})^2 / 4 \times \Delta t \sim \frac{p_{\perp}^2 V^2}{6L \max(v_A, u)} \quad (7)$$

where we adopted the GS95 scaling for the pseudo-Alfvén modes, $v_k \sim V(k_L L)^{-1/3}$ and $k_{\parallel} \sim k_{\perp}^{2/3} L^{-1/3}$, V is the turbulence velocity at the injection scale L of MHD turbulence. For pseudo Alfvén modes, $\mathbf{v}_k \perp \mathbf{k}$ and resides in the $\mathbf{k} - \mathbf{B}$ plane. Moreover most energy is concentrated in the modes with $\mathbf{k} \perp \mathbf{B}$ in the GS95 model. Therefore we used $v_{k,\parallel} \simeq v_k$ in the above equation. Unlike cosmic rays, $\Delta t = 1/[k_{\parallel} \max(v_A, u)]$ is determined by the minimum of the

eddy turnover time and the particle streaming time. This is because the scattering of grains are infrequent because of the low speed as pointed out in YL03.

3.2 Acceleration in compressible turbulence

In compressible medium, there are both slow modes and fast modes. For compressible modes, the above mechanism also operates on the scale $l < l_{mfp}$. The compression on large scale $l > l_{mfp}$ is much less efficient in accelerating grains for the following reason. Since usually $l_{mfp} \gg r_g$, $l > l_{mfp}$ indicates $l \gg r_g$. Lack of sufficient scattering the adiabatic invariant of grain $v_{\perp}^2/B$ is conserved in this case and the change of grain velocity is only a factor of few (Cho & Lazarian 2006).

The betatron acceleration by fluctuations on $l < l_{mfp}$ does not work for small grain, whose mean free path is less than the turbulence damping scale l_c . Lack of scattering, the mean free path of dust is usually determined by the gaseous or plasma drag $l_{mfp} = ut_{drag}$.

Let us consider the betatron acceleration by the compressible modes on the small scales $l < l_{mfp}$. The first term in Eq.(4) is nonzero and needs to be accounted for.

$$\begin{aligned} \bar{E} &= \frac{1}{2\pi r_g} \int (\nabla \times \mathbf{E}) \cdot d\mathbf{s}, \\ &= \frac{1}{2\pi r_g c} \int [\nabla \times (\mathbf{v} \times \mathbf{B})] \cdot d\mathbf{s}, \\ &\approx \frac{k_{\perp} v_{k,\perp} B_0 r_g}{2c}, \end{aligned} \quad (8)$$

where $v_{k,\perp}$ is the fluid velocity perpendicular to the magnetic field. Accordingly, the electrical force and the momentum diffusion coefficient are

$$\frac{dp}{dt} = q\bar{E} = k_{\perp} v_{k,\perp} p_{\perp} / 2, \quad (9)$$

$$D_p = \left(\frac{dp}{dt} \right)^2 \Delta t \sim k_{\perp}^2 p_{\perp}^2 v_{k,\perp}^2 \min(t_{wav}, t_{gc}) / 4, \quad (10)$$

where t_{wav} is the wave period and t_{gc} is the confinement time of the grains.

For slow modes,

$$D_{p,k} = \frac{k_{\perp}^{2/3} L^{-1/3} p_{\perp}^2 V^2}{4 \max(v_{ph}, u)} < \frac{v_{k,\perp}^2}{v_k^2} >, \quad (11)$$

where $v_{ph} = \min(v_A, c_S)$ is the phase speed of the slow modes. The velocity displacement of slow modes is in the direction of $\hat{\mathbf{k}}_{\parallel} - \frac{\beta}{2} \sin \theta \cos \theta \hat{\mathbf{k}}_{\perp}$ and $\perp \mathbf{k}$ in the high β medium (Cho & Lazarian 2006), where θ is the wave pitch angle, i.e., the angle between the wave vector $\mathbf{k}$ and $\mathbf{B}$, $\beta = 2c_s^2/v_A^2$ is the ratio of thermal pressure to magnetic pressure. Therefore, $\langle v_{k,\perp}^2/v_k^2 \rangle \approx \langle \cos^2 \theta \rangle$ in high β medium and $\langle v_{k,\perp}^2/v_k^2 \rangle \approx \beta^2 < \sin^2 \theta \cos^2 \theta \rangle / 4$ in low β medium. Because of the strong anisotropy ($k_{\perp} \gg k_{\parallel}$), $\langle \sin^2 \theta \rangle \approx 1$, and $\langle \cos^2 \theta \rangle \approx (k_{\parallel}/k_{\perp})^2 = (k_L L)^{-2/3}$. All the scales from l_{mfp} to the truncation scale l_c contribute to the acceleration. Since the contribution from the scales smaller than the gyroradius has been included in the treatment of gyroresonance in YL03, we only account for the eddies larger than gyroradii. Integrating Eq.(11), we get

Figure 1. (a): the compression of magnetic field induce a nonzero curl of electric field, which accelerate grains as grains are orbiting around the magnetic field; (b): the direction of velocity perturbation and electric field induced by compressible modes.

$$D_p \sim \frac{p^2 V^2}{6L \max(v_{ph}, u)} \min\left(\frac{\beta^2}{4}, 1\right) \ln\left[\frac{l_{mfp}}{\max(l_c, r_g)}\right] \quad (12)$$

In low β medium, the slow modes cause marginal compression of magnetic field with the velocity perturbations being nearly parallel to the magnetic field. That is why the acceleration by the slow modes in the low β regime is substantially reduced.

For *fast* modes, the velocity perturbation is $\perp \mathbf{B}$ in the low β case and $\parallel \mathbf{k}$ in the high β case and therefore $v_{k,\perp}^2/v_k^2 \approx 1$ for $\beta < 1$ and $2/3$ for $\beta > 1$ since fast modes are isotropic. Unlike slow modes, the cascade of fast modes is slower, namely, the cascading time is longer than the wave period. Therefore, one needs to take into account periodic motion of the fast modes. In case when particles are confined in the eddy longer than the wave period, the expansion ensuing the compression will take the energy back from the particles. Therefore, the acceleration only happens if the particles leave the eddies within one compressional period. Since grains experience marginal scattering, it indicates that only super-Alfvénic grains ($\beta < 1$) or supersonic grains ($\beta > 1$) can be accelerated.

$$D_p = \left(\frac{dp}{dt}\right)^2 \Delta t \sim k_{\perp}^2 p_{\perp}^2 v_{k,\perp}^2 t_{gc}/4 \sim k^{1-2\xi} L^{-2\xi} p_{\perp}^2 V^2/(6u), \quad (13)$$

where we have used $v_k = (kL)^{-\xi}$, $\xi = 1/3$ for Kolmogorov turbulence and $1/4$ for acoustic turbulence. Unless otherwise specified, we adopt $\xi = 1/4$ to enable comparison with our earlier results (YL03, YLD04). Since it increases with the wave number k , the contribution on the smallest possible scale is dominant. Excluding the contributions from scales $\lesssim r_g$, the corresponding scale is then $\max(r_g, l_c)$. Accordingly,

$$D_p \sim \frac{p^2 V^2}{9u \max(r_g, l_c)^{1-2\xi} L^{2\xi}}. \quad (14)$$

Comparing the above equations, we see that usually the acceleration by fast modes is much more efficient than by slow modes. Low speed grains, however, can only be accelerated by the slow modes for the reason we discussed above.

4 ALTERNATIVE ACCELERATION MECHANISMS

4.1 Gyroresonance

Gyroresonance acceleration of charged grains by a spectrum of MHD waves decomposed into incompressible Alfvénic, and compressible fast and slow modes (see CL02) was first described in Yan & Lazarian (2003). Gyroresonance occurs when the Doppler shifted frequency of the wave in the grain's guiding center rest frame $\omega_{gc} = \omega - k_{\parallel} u_{\parallel} = n\Omega$ is a multiple of the grain gyrofrequency, $u_{\parallel}$ is the component of grain velocity parallel to the local magnetic field. For low speed grains, we only need to consider the resonance at $n = 1$. From the resonance condition, we see that gyroresonance requires perturbations on the Larmor scale and therefore only applicable to large grains whose gyroradii are larger than the dissipation scale of the turbulence l_c . The gyroresonance changes both the direction and absolute value of the grain's momentum (i.e., scatters and accelerates the grain). The ratio of the scattering and acceleration rates is approximately u^2/v_A^2 . For low speed grains, therefore, acceleration is the main effect.

4.2 Transit time damping

In the calculations in §3, we neglected the mirror force $-\mu \nabla B = -mu_{\perp}^2 \nabla B/(2B)$, which scatters the grains, but does not increase the energy. In the small amplitude limit $\delta B \ll B$, particles should keep in phase with the wave $k_{\parallel} v_{\parallel} = \omega$ in order to have effective interactions with the compressions of magnetic field. This process is often referred as transit time damping (TTD) in the literature (see, e.g., Achterberg 1981; Schlickeiser & Miller 1998; Yan & Lazarian 2004). In this case, the mirror force redirect the energy gain in the perpendicular direction to the parallel direction without changing the total grain speed. In fact, our test calculation of the TTD using quasilinear approach is consistent with the results in §3 within order of unity. I therefore do not think that in terms of the acceleration TTD is different from the betatron process discussed in this paper.

4.3 Hydrodynamic drag

In hydrodynamic turbulence, the grains motions are caused by the frictional interactions with the gas. On large scales grains are coupled with the ambient gas, and the slowing fluctuating gas motions will only cause an overall advection of the grains with the gas (Draine 1985), which we are not interested. On small scales grains are decoupled. The largest velocity difference occurs on the largest scale where grains are still decoupled. Thus the characteristic velocity of a grain with respect to the gas corresponds to the velocity dispersion of the turbulence on the time scale t_{drag} . In the MHD case, the grain perpendicular motions are constrained by the Larmor gyration unless $t_{drag}\Omega < 1$ (Lazarian & Yan 2002).

The grain motions get modified when the damping time scale of the turbulence τ_c is longer than either t_{drag} or $1/\Omega$. In this case, a grain samples only a part of the eddy before gaining the velocity of the ambient gas. The largest shear appears on the damping scale, and thereby $u \sim v_c \min(1/\Omega, t_{drag})/\tau_c$, where v_c is the velocity on damping time scale τ_c .

4.4 Ponderomotive force

A cross-field acceleration by the ponderomotive force was suggested by Shukla & Stenflo (2005) as an another independent mechanism in turbulence to provide grains with supersonic speeds. If this were true, it would indeed indicate a dramatic shift in the whole scenario, especially for small grains. We find however their formalism is erroneous. Let us start from the electric field that could arise in the varying magnetic field. Considering the momentum equation of the electron, where the electron inertia can be neglected in the low frequency MHD regime,

$$n_e e \mathbf{E} = -\frac{n_e e}{c} \mathbf{v}_e \times \mathbf{B} - \gamma_e T_e \nabla n_e, \quad (15)$$

where n_e , $\mathbf{v}_e$, T_e , γ_e are the density, velocity, temperature and adiabatic index of electrons. Combining it with the quasi-neutrality condition $n_e = n_i + Z n_d$ and the induction equation,

$$\nabla \times \mathbf{B} = \frac{4\pi e}{c} (n_i \mathbf{v}_i + Z n_d \mathbf{u} - n_e \mathbf{v}_e), \quad (16)$$

we obtain

$$\mathbf{E} = \frac{1}{n_e e} \left(\frac{\nabla \times \mathbf{B}}{4\pi} - n_i \mathbf{v}_i - Z n_d \mathbf{u} \right) \times \mathbf{B} - \gamma_e T_e \nabla n_e \quad (17)$$

where n_i , $\mathbf{v}_i$ are the density and velocity of ions. If we neglect the thermal term in the low β medium we consider, the electric field is perpendicular to the magnetic field and cannot accelerate the particles longer than the Larmor period. The net effect of the electric field is to induce a drift in the direction $\mathbf{E} \times \mathbf{B}$. The corresponding drift speed is

$$\mathbf{u} = c \frac{\mathbf{E} \times \mathbf{B}}{B^2} = \mathbf{v}_i - \frac{c \mathbf{k} \times \delta \mathbf{B}}{4\pi n_e e} \quad (18)$$

Since the acceleration is on the time scale of Larmor period, the wavenumber in the above equation is given by $k \approx r_g^{-1}$ and ion velocity that should be adopted is the velocity of the ions (gas) on the Larmor scale. It turns out then the second term is much less than the first term in the above equation, and the drift is in fact the same process as the gaseous drag we already accounted for in Lazarian & Yan (2002) and also the Fig.1 in this paper. In other

words, there is no such an additional ponderomotive acceleration as discussed in Shukla & Stenflo (2005).

4.5 Weak shocks

Simulations indicate that the density structures in supersonic MHD turbulence are associated with slow shocks (Beresnyak, Lazarian, & Cho 2005). Therefore in supersonic turbulence, one also needs to take into account the contribution of grain acceleration from shocks (Epstein 1980; McKee et al. 1987; Ellison et al. 1997). The shocks in the supersonic turbulence require better quantitative description, nevertheless.

4.6 H_2 rocket and radiative pressure

A different mechanism of driving grain motions is a residual imbalance in “rocket thrust” between the opposite surfaces of a rotating grain (Purcell 1979). This mechanism can provide grain relative motions and preferentially move grains into molecular clouds. Three causes for the thrust were suggested by Purcell (1979): spatial variation of the accommodation coefficient for impinging atoms, photoelectric emission, and H_2 formation. The latter was shown to be the strongest among the three. The uncompensated force in this case arises from the difference of the number of catalytic active sites for H_2 formation on the opposite grain surfaces. The nascent H_2 molecules leave the active sites with kinetic energy E and the grain experiences a push in the opposite directions. H_2 thrust potentially may be important for small grains. In the typical interstellar environment, small grains flip frequently according to recent study (Hoang & Lazarian 2009). As a result, the thrusts are smeared out.

Dust grains exposed to anisotropic interstellar radiation fields are subjected to forces as well as torques (Purcell 1979; Weingartner & Draine 2001a). These forces arise from photoelectric emission, photodesorption as well as radiation pressure. Weingartner & Draine (2001a) considered the forces and calculated the drift velocity for grains of different sizes. The velocities resulted from these processes, however, are smaller than those arising from interactions with turbulence in the interstellar medium (YLD04).

5 RESULTS

To compare with earlier work (YLD04), we consider first the warm ionized medium (hereafter WIM) with the same parameters, $T = 8000\text{K}$, $n_e = 0.1\text{cm}^{-3}$, $B_0 = 3.35\mu\text{G}$ (see table5). Here, we consider grains in the range of $10^{-7}\text{cm} < a < 10^{-4}\text{cm}$, which carry most grains mass in ISM. We adopt the mean grain charge as given in YLD04, which was obtained by balancing the collisions with electrons and collisions with ions as well as photoelectric emission (Weingartner & Draine 2001b). We assume that for MHD turbulence the injection of energy happens at the scale L where the equipartition between magnetic and kinetic energies, i.e., $V = V_A$, is reached. If we adopt a velocity dispersion $\delta V = 40\text{km/s}$ at the scale $l = 30\text{pc}$, then turbulence in WIM is super-Alfvénic at this scale. If turbulence at this regime follows hydrodynamic cascade, then L is 3.75pc where the injection velocity is $V = V_A = 20\text{km/s}$. The acceleration is dominated by the interactions with fast modes. Since fast modes are long lived and can only accelerate particles whose crossing time is shorter than the wave period, the betatron

acceleration only operates with fast-moving large grains. The result for the WIM is demonstrated in Fig.2, where the outcome from different grain acceleration processes are compared.

Next we consider a warm neutral medium (hereafter WNM), with $T=6000\text{K}$, $n_H = 0.3\text{cm}^{-3}$, $B_0 = 5.8\mu\text{G}$ and the same turbulence injection velocity and scale as in WIM (see table 1 for other parameters). In partially ionized medium, a viscosity caused by neutrals results in decoupling on the characteristic time scale (Lazarian & Yan 2002) $t_{damp} \sim v_n^{-1}k^{-2} \sim (l_n v_n)^{-1}k^{-2}$, where v_n is the kinetic viscosity, l_n is the neutral mean free path, v_n is the thermal velocity of neutrals. When its cascading rate τ_k^{-1} equals to the damping rate t_{damp}^{-1} , turbulence is considered damped. This defines the truncation scale of the turbulence l_c . $\tau_k = kV^2/v_{ph}$ for fast modes (Cho et al. 2002) and $\tau_k = k_{\perp}^{2/3}L^{-1/3}v_A$ for Alfvén and slow modes (Goldreich & Sridhar 1995). Then for WNM, one gets $l_c \simeq 8.3 \times 10^{15}\text{cm}$ for the fast modes and $l_c \simeq 5.3 \times 10^{17}\text{cm}$ for Alfvén and slow modes. This introduces a cutoff grain size for the acceleration by fast modes, for which the Larmor period is equal to the damping time scale. The result for grain acceleration is shown in Fig.2. As we see, the betatron acceleration operates for an extended range of grains and can be more efficient compared to gyroresonance. In particular, fast modes accelerate further the super-Alfvénic grains and slow modes dominant the acceleration for the smaller grains.

In YL03, we proposed gyroresonance as one important acceleration mechanism for grain dynamics. We showed that the magnetostatic approximation for turbulence is invalid for grains, whose velocities are less or comparable to the velocity perturbations in turbulence. As a result, the resonance function in the quasi-linear theory is broadened from the resonance wavenumber $k_{\parallel, res} \sim 1/r_g$ to all k in the inertial range. To cut off the spurious resonance contribution from the large scale perturbations, we truncated the integration for the momentum diffusion at the $k_{\parallel, res}$ and discarded all the interactions from the larger scales. A complementary study is conducted in this paper to include the acceleration from the large scales. Our results show that the nonresonant interaction is comparable to the gyroresonance and can get even more efficient in super-Alfvénic turbulence and the strength of magnetic field.

Our results show that only large grains can be effectively accelerated by the large scale compressions in turbulence. It is due to the fact that the scattering of grains is marginal. With the ballistic motions, the adiabatic invariant is conserved provided that the grain gyroradii are much smaller than the turbulence injection scale. The grain energy gain is thus limited. For large grains, their gyroradii are close to perturbation scale and there is no such a constraint. Our results are therefore self-consistent.

How would the results vary as the parameters of the partially ionized medium vary? The relative importance of the gyroresonance and betatron acceleration depends on the magnitude of the magnetic field as well as the intensity of turbulence. With the increase of magnetic field, the relative efficiency of betatron acceleration decreases compared to gyroresonance. On the other hand, the betatron acceleration increases faster with the intensity of turbulence than gyroresonance. More specifically, gyroresonance dominates in equipartition turbulence and sub-Alfvénic turbulence ($M_A = \delta V/v_A \lesssim 1$). In super-Alfvénic turbulence ($M_A = \delta V/v_A > 1$), betatron acceleration becomes important and works for extended range of grains being less constrained by the turbulence damping. In §5, for instance, we adopt $\delta V = 40\text{km/s}$ at $l = 40\text{pc}$. If one takes $\delta V = 20\text{km/s}$ as in YLD04, the nonresonant and resonant acceleration rates are comparable. It is therefore sufficient to

consider only the gyroresonance. Although turbulent generation of magnetic field tend to bring kinetic and magnetic energy to equipartition, the time required is long (a few crossing time at the injection scale according to Cho et al. 2008), during which grains can be accelerated through the betatron process with the super-Alfvénic turbulence. Even if the velocity dispersions that we adopt in table.1 are excessive for the entire ISM, the local driving may bring them to such and even larger values.

6 DISCUSSIONS

This paper intends to encompass all possible situations where dust grains can be accelerated. As presented in §4, various processes have been proposed in the literature for the grain acceleration. In regard to the plasma processes alone, there have been shock acceleration (e.g., Epstein 1980; McKee et al. 1987), gyroresonance (Yan & Lazarian 2003), ponderomotive force (Shukla & Stenflo 2005). We intend to supplement the list by taking into account nonresonant betatron acceleration in MHD turbulence. This process was discussed in the context of cosmic ray acceleration (e.g., Ptuskin 1988; Cho & Lazarian 2006), but has not been considered for charged grains. The study here demonstrates that the betatron acceleration can be important in super-Alfvénic turbulence.

The steady state for the strongly super-Alfvénic turbulence is not achievable due to dynamo generation. However, numerical simulations (see Cho et al. 2008) show that the steady state may not necessarily have the exact equipartition and kinetic energy may sometimes dominate. In fact, even in the situation when turbulence in terms of its mean velocity dispersion in the volume is sub-Alfvénic, density fluctuations may induce super-Alfvénic turbulence. This is shown in Burkhart et al. (2008).

It has been shown that the composition of the galactic cosmic ray seems to be better correlated with volatility of elements (Ellison, Drury, & Meyer 1997). The more refractory elements are systematically overabundant relative to the more volatile ones. This suggests that the material locked in grains must be accelerated more efficiently than gas-phase ions (Epstein 1980; Ellison, Drury, & Meyer 1997). The stochastic acceleration of grains, in this case, can act as a preacceleration mechanism. The accelerated grains are more efficiently scattered by MHD perturbations, which is a key component for diffuse shock acceleration.

Grains moving supersonically can efficiently vacuum-clean heavy elements as suggested by observations (Wakker & Mathis 2000). Grains can also be aligned if the grains get supersonic (see review by Lazarian 2007). The supersonic grain motions will result in grain alignment with long axes perpendicular to the magnetic field. In fact, for irregular grains with nonzero degree of helicity, even subsonic motions can get grains aligned as recently illustrated by Lazarian & Hoang (2007). The critical velocity is, however, still unclear. If taking into account mirror reflection, the energy gain of grains is not strictly in the perpendicular direction. Nevertheless, fast moving grains are aligned with the long axes perpendicular to the magnetic field regardless of its direction of motions according to recent studies (Lazarian & Hoang 2007).

In our recent paper Hirashita & Yan (2009), we calculated the equilibrium grain size distribution based on our earlier result (YLD04) and obtained corresponding extinction curve in various phases of ISM. There we applied the gyroresonance, which is dominant in equipartition turbulence and sub-Alfvénic turbulence. We believe the bulk of interstellar medium has $M_A \lesssim 1$ because of the

	$T(K)$	$n_H(\text{cm}^{-3})$	$n_e(\text{cm}^{-3})$	G_{UV}	$B(\mu G)$	$L(\text{pc})$	$V = v_A(\text{km} \cdots^{-1})$	$l_c(\text{cm})$
WIM	8000	0.1	0.0991	1	3.35	3.7	20	...
WNM	6000	0.3	0.03	1	5.8	3.7	20	8.3×10^{15}

Table 1. The parameters of idealized ISM phases and relevant damping. Among them, n_H is the number density of H, n_e is the number density of electron, G_{UV} is the UV intensity scale factor, V is the injection velocity. L is the injection scale of fast modes, which is taken as the scale where the turbulence velocity is equal to the Alfvén speed (see the text for details). The dominant damping mechanisms for fast modes are given with the corresponding damping timescale τ_c . WNM=warm neutral medium, WIM=warm ionized medium.

Figure 2. Grain velocity vs. size owing to different acceleration processes in WIM (left) and WNM (right). The result from betatron acceleration is represented by the dashed line. The ‘.’ line represents the gyroresonance with fast modes. The dash-dot line is the result from hydro drag with fast modes. The dotted line refers to the threshold velocity for coagulation. Contributions from different processes are approximately additive as shown by the solid line.

dynamo process, the basic conclusion there is valid therefore. In particular environments where turbulence gets super-Alfvénic, the process discussed in this paper should be accounted for. As I discussed earlier, the betatron acceleration is most efficient for large grains ($> \text{a few tenths } \mu\text{m}$), so the effect is mainly on shattering. Depending on the intensity of turbulence and the strength of magnetic field, the velocity can be increased by a factor of a few through the betatron acceleration, which could decrease the upper limit of the grain size in the warm media by a factor of few. In cold media, including cold neutral medium and the molecular clouds, the betatron acceleration is less efficient, for two reasons. First, the low levels of UV and low temperatures result in reduced grain charge. Secondly, because of the increased density, the frictional drag is increased. The betatron process is subdominant unless in highly super-Alfvénic turbulence, which could appear in a transient state.

7 SUMMARY

We calculate the acceleration of charged grains arising from betatron acceleration by MHD turbulence. We used the CL02’s results for the description of MHD turbulence, according to which Alfvénic turbulence and slow modes follows GS95 scaldings while fast modes are isotropic. We obtained estimates of grain velocities in interstellar medium. We showed that

- (i) MHD turbulence dominate grain acceleration in interstellar medium.
- (ii) The relative importance of betatron acceleration and gyroresonance depends on the intensity of turbulence. While gyrores-

onance dominates in sub-Alfvénic turbulence, betatron acceleration can be important in super-Alfvénic turbulence.

- (iii) Nonresonant acceleration with fast modes are important for large grains in warm media. Slow modes can accelerate sub-micron grains through the nonresonant interactions.

- (iv) Grain velocities depend on the local conditions of turbulence.

- (v) Dust gets supersonic via interactions with interstellar turbulence. The velocities obtained are sufficiently high to be important for shattering large grains and efficiently absorbing heavy elements from gas. The acceleration can also result in mechanical alignment of grains perpendicular to the magnetic field.

ACKNOWLEDGMENTS

I thank A. Lazarian for reading the manuscript and valuable comments and suggestions. Helpful discussions with J. Cho is acknowledged. This work is supported by Arizona Prize Fellowship.
